Overview of Regression

- Bayesian learning framework, maximum *a posteriori* (MAP)
  - ⋆ type-II maximum likelihood or evidence procedure
  - ⋆ Markov chain Monte Carlo sampling
  - ⋆ variational learning method
- Kernel-based data modelling
  - ⋆ support vector machines (structural risk minimisation)
  - ⋆ relevance vector machines (individual hyperparameters)
- Parsimonious principle, subset model selection
  - ⋆ OLS: significance of individual selected terms

$\Rightarrow$ *OLS with individual regularisation to enforce sparsity.*

Regression Model

$$y(k) = \hat{y}(k) + e(k) = \sum_{i=1}^{n_M} \theta_i \phi_i(k) + e(k), \ 1 \leq k \leq N$$

$y(k)$: target or desired output, $e(k) = y(k) - \hat{y}(k)$, $\hat{y}(k)$: model output, θ_i: model weights, $\phi_i(k)$: regressors, n_M: number of candidate regressors, N: number of training samples. Defining

$$\mathbf{y} = [y(1) \cdots y(N)]^T, \quad \mathbf{e} = [e(1) \cdots e(N)]^T, \quad \boldsymbol{\theta} = [\theta_1 \cdots \theta_{n_M}]^T$$

$$\boldsymbol{\Phi} = [\boldsymbol{\Phi}_1 \cdots \boldsymbol{\Phi}_{n_M}] \quad \text{with} \quad \boldsymbol{\Phi}_i = [\phi_i(1) \cdots \phi_i(N)]^T$$

leads to matrix form

$$\mathbf{y} = \boldsymbol{\Phi}\boldsymbol{\theta} + \mathbf{e}$$

Orthogonalisation

Orthogonal decomposition: $\mathbf{\Phi} = \mathbf{WA}$, where

$$\mathbf{A} = \begin{bmatrix} 1 & a_{1,2} & \cdots & a_{1,n_M} \\ 0 & 1 & \ddots & \vdots \\ \vdots & \ddots & \ddots & a_{n_M-1,n_M} \\ 0 & \cdots & 0 & 1 \end{bmatrix}$$

and $\mathbf{W} = [\mathbf{w}_1 \cdots \mathbf{w}_{n_M}]$ with orthogonal columns: $\mathbf{w}_i^T \mathbf{w}_j = 0$, if $i \neq j$.

Regression model becomes

$$\mathbf{y} = \mathbf{Wg} + \mathbf{e}$$

with orthogonal weight vector $\mathbf{g} = [g_1 \cdots g_{n_M}]^T$ satisfying

$$\mathbf{A}\boldsymbol{\theta} = \mathbf{g}$$

Locally Regularised Regression

Given regularisation parameter vector $\boldsymbol{\lambda} = [\lambda_1 \cdots \lambda_{n_M}]^T$ and denoting $\boldsymbol{\Lambda} = \text{diag}\{\lambda_1, \cdots, \lambda_{n_M}\}$, locally regularised error criterion:

$$J_R(\mathbf{g}, \boldsymbol{\lambda}) = \mathbf{e}^T\mathbf{e} + \mathbf{g}^T\boldsymbol{\Lambda}\mathbf{g} = \mathbf{y}^T\mathbf{y} - \sum_{i=1}^{n_M} \left(\mathbf{w}_i^T\mathbf{w}_i + \lambda_i\right) g_i^2$$

• Forward-regression procedure selects significant regressors according to regularised error reduction ratio due to each regressor $\mathbf{w}_i$

$$[\text{rerr}]_i = \left(\mathbf{w}_i^T\mathbf{w}_i + \lambda_i\right) g_i^2 / \mathbf{y}^T\mathbf{y}$$

Selection terminated with n_s-term sub-model at the n_s-th stage when

$$1 - \sum_{l=1}^{n_s} [\text{rerr}]_l < \xi$$

Regularisation Parameter Update

• Based on Bayesian evidence procedure, iterative loop for updating regularisation parameters:

$$\lambda_i^{\text{new}} = \frac{\gamma_i^{\text{old}}}{N - \gamma^{\text{old}}} \frac{\mathbf{e}^T \mathbf{e}}{g_i^2}, \quad 1 \leq i \leq n_M$$

where

$$\gamma_i = \frac{\mathbf{w}_i^T \mathbf{w}_i}{\lambda_i + \mathbf{w}_i^T \mathbf{w}_i} \quad \text{and} \quad \gamma = \sum_{i=1}^{n_M} \gamma_i$$

Special cases of this LROLS —

⋆ Original OLS: $\lambda_i = 0$, $\forall i$

⋆ UROLS: $\lambda_i = \lambda$, $\forall i$

A Simple Example

Modelling $f(x)$ given $y = f(x) + \epsilon$ and x. 100 x uniform distribution in $(0,\ 1)$ and ϵ zero mean Gaussian with variance 0.16.

The RBF Gaussian kernel function with variance of 0.04. Each training data was considered as a candidate RBF center and $n_M = 100$.

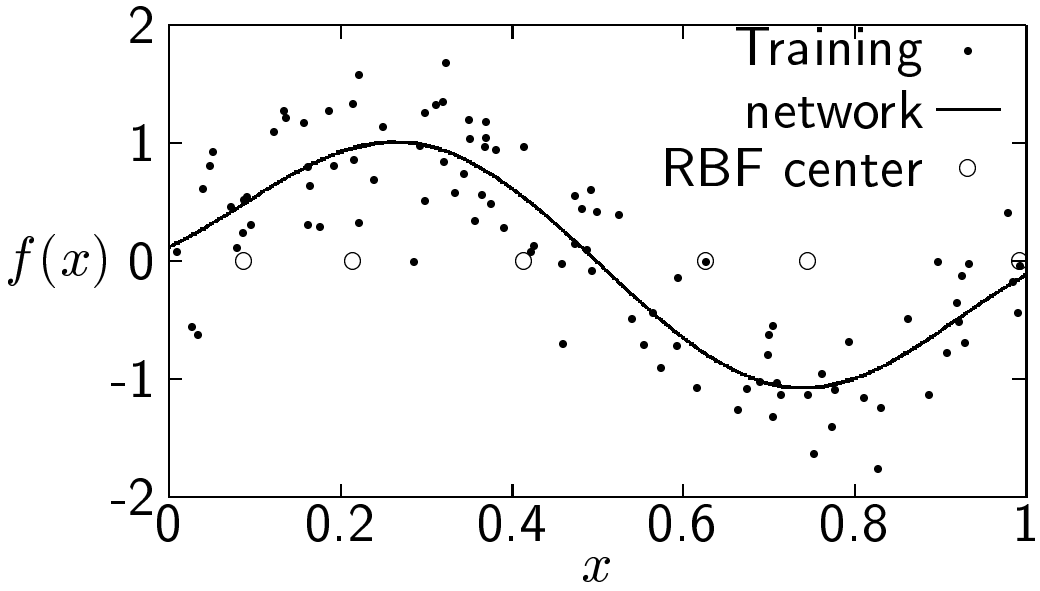
LROLS Modelling Result



6-term model mapping (curve) produced by the LROLS algorithm for the simple scalar function modelling problem. Dots indicate noisy training data y and circles the RBF centers.

Conclusions

- Parsimonious principle based subset model selection
  - ⋆ OLS algorithm selects significant model terms
- Local regularisation re-enforces sparsity of selected model
  - ⋆ When to terminate subset model selection becomes obvious
- Combined algorithm is very efficient and capable of producing small-size models that generalize well
